Looking at the following plot shows that suicide does increase when single parenthood increased, although not by too much

Looking at the following plot shows that rates of living alone have a steady rate on increasing male suicide rate, but not much for female suicide

Looking at the following plot shows that increased GDP per capita reduces suicide rates across the board, though once out of poverty, has almost no effect

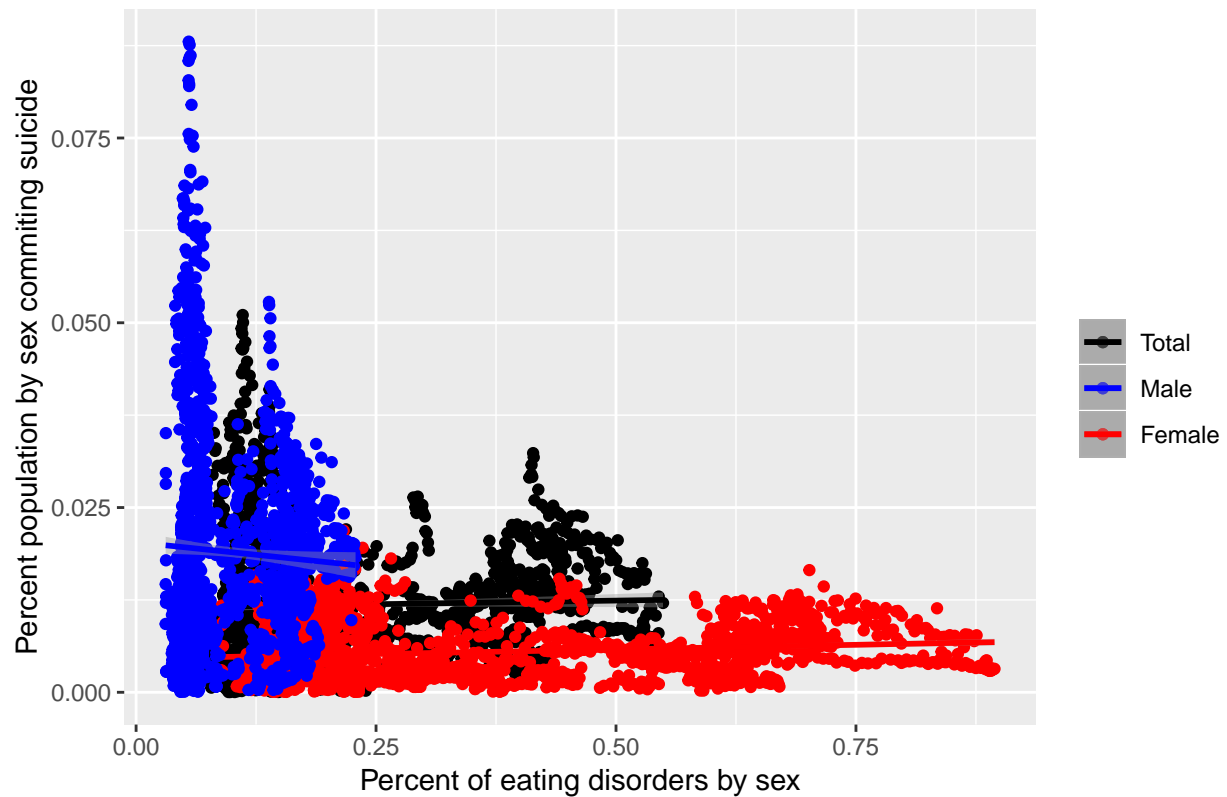

Looking at the following plot shows that suicide rates increase as countries develop, but not by a significant amount

Looking at the following plot shows that eating disorders have almost no correlation to suicide rates on either sex.

Eating Disorder's Effect on Suicide Rates

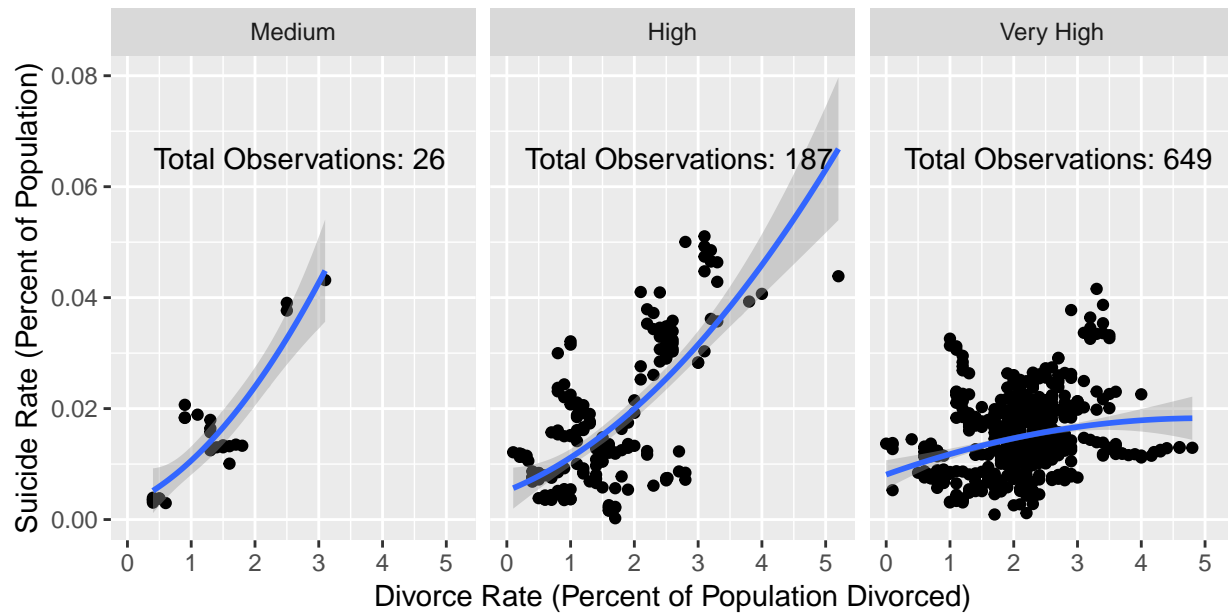

Formal Visualizations

Male vs Female Suicide Rates: This scatter plot displays the male suicide rate as a percentage of the male population and the female suicide rate as a percentage of the female population. The blue line is a line of best fit with a polynomial degree of 1. The red line is the 'y=x' line where the female suicide rate will equal the male suicide rate. As we can see, when suicide rates increase in males, they increase for their female counterparts as well. However, suicide appears to be a primarily male problem. Very few countries have had at least one year where the female suicide rate is higher than the male, and all of them have had extremely low suicide rates in general. This chart suggests that most, if not all, suicide risk factors apply to both males and females, but that the magnitude of any risk factor will be felt more severely by the male population.

Correlation of Divorce Rates and Suicide Rates: This faceted scatter plot displays the divorce rate as a percent of the population that is divorced, to the suicide rate as a percent of the population. The blue line is a line of best fit with a polynomial degree of 2. The facets divide the scatter plot into different levels of human development according to the Human Development Index. As we can see there is a strong trend that as divorce rates increase, suicide rates do as well. However, it is clear that this trend is much more pronounced in lesser developed countries. This may suggest that divorce is more normal in very high developed countries and that there are better societal structures in place to deter suicide in this instance.

Correlation of Divorce Rates and Suicide Rates Grouped by Human Development Index (HDI)

Based on data from WHO's Suicide Database, OECD's Family Database, UNDR's Human Development Index.

Suicide rates include only successful attempts.

Medium Development is classified as greater than or equal to 0.55 HDI.

High Development is classified as greater than or equal to 0.7 HDI.

Very High Development is classified as greater than or equal to 0.8 HDI.

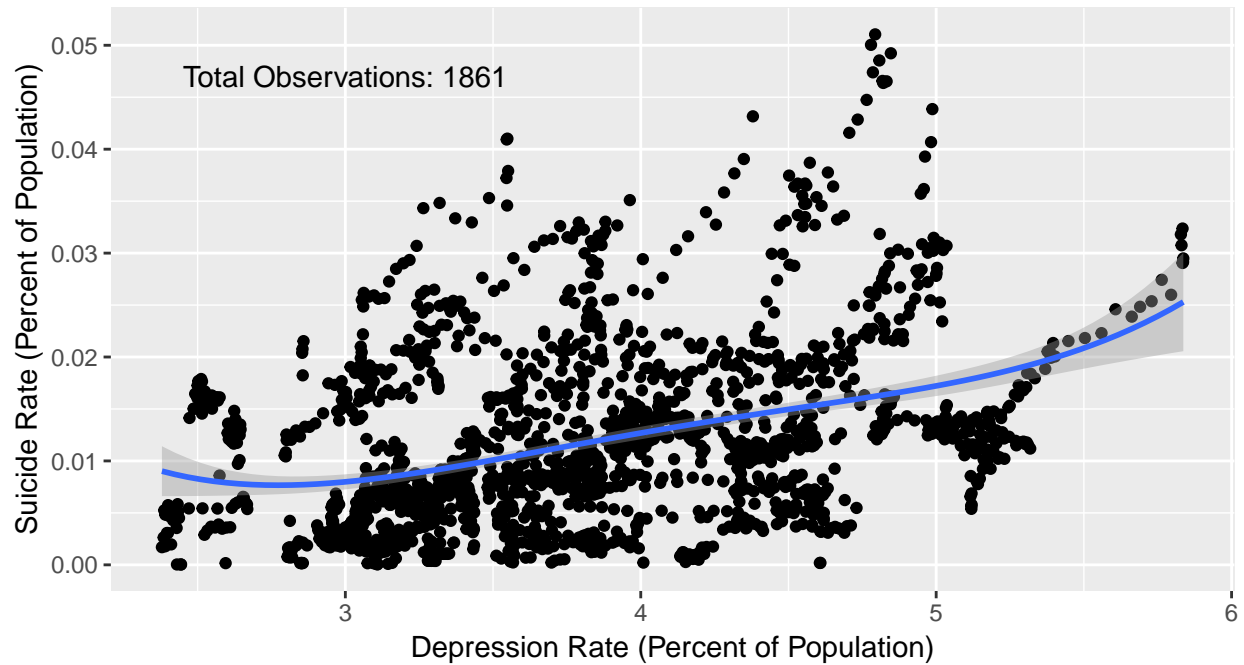

Correlation of Population Growth and Suicide Rate : This scatter plot displaces the annual percent of population growth with the suicide rate as a percent of the population. The blue line is a line of best fit with a polynomial degree of 2. This plot shows a strong trend that at low rates of population growth that higher rates deter suicide. Due to the majority of reporting countries being at very low population growths, the higher rates (higher than 7% population growth) were extremely under represented and were removed as outliers.

Correlation of Population Growth and Suicide Rate By Country Year

Correlation of Depression and Suicide Rates: This scatter plot displays the Depression rate as a percentage of the population with the suicide rate as a percentage of the population. The blue line is a line of best fit with a polynomial degree of 4. This plot shows a strong trend that as Depression rates increase, suicide rates do as well. However, this trend is not as strong as one would expect, and there are plenty of countries that appear to have a much higher suicide rate with even low depression rates. While these Depression rates were adjusted by OWID to account for underdiagnosis, this may suggest that the underdiagnosis is more extreme than they predicted. If not, then that would suggest that suicide and depression are not perfect proxies of each other, and that a sizable proportion of suicides are committed by people without Depression.

Correlation of Depression and Suicide Rates By Country Years

Based on data from WHO's Suicide Database and OWID's Mental Health Article
 Suicide rates include only successful attempts
 Depression rates are approximated and were adjusted due to predicted underdiagnosis.

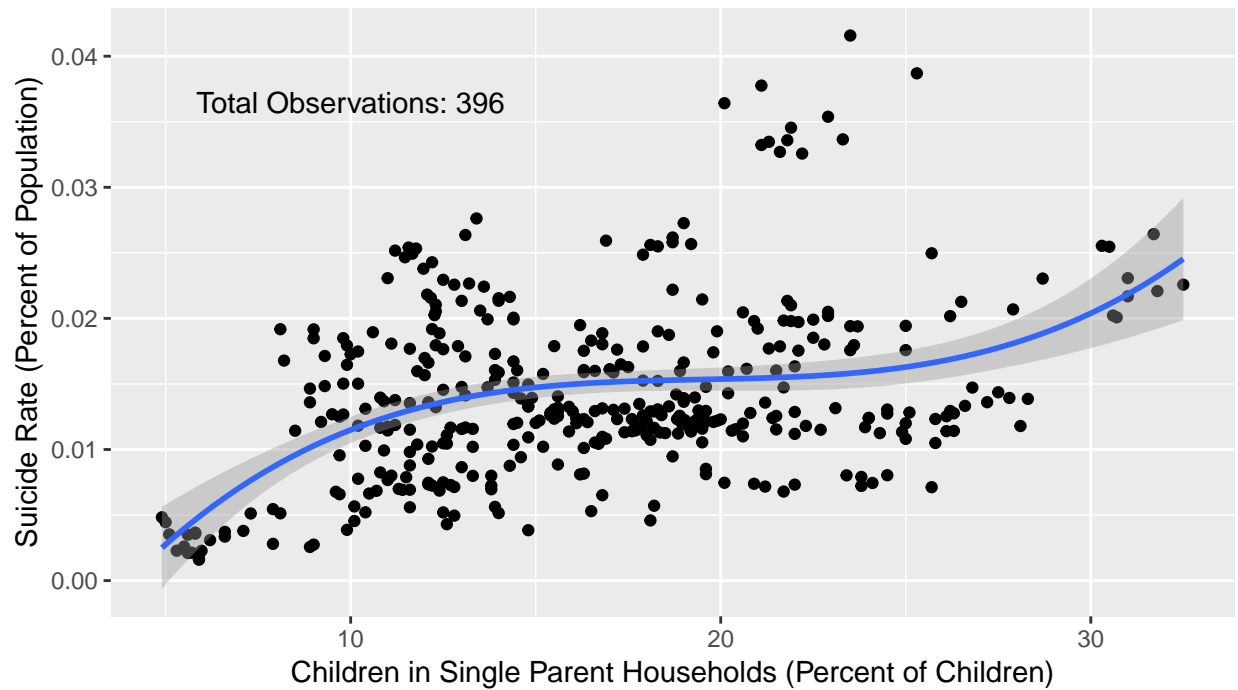

Correlation of Two and Single Parent Households to Suicide Rates: These two plots display the percent of children in a two parent household, or a single parent household, respectively to the suicide rate as a percent of the population. The blue line is a line of best fit with a polynomial degree of 3. These two plots appear to be mirror images of each other as they are measuring similar things. However children can also be in foster care, homeless, no parent households (raised by siblings), and other situations, which are not included in either plot. Thus these two plots are not perfect inverses of each other. As you can see, there is a clear trend that suicide rates increase as rates of single parent households increases, and decreases as rates of two parent households decreases. This correlation appears to plateau in the middle. This is due to the countries in that area collecting data over a longer period of time, and thus having more points in the scatter plot.

Correlation of Two Parent Households and Suicide Rates
By Country Years

Based on data from WHO's Suicide Database and OECD's Family Database.
Suicide rates include only successful attempts.

Correlation of Single Parent Households and Suicide Rates By Country Years

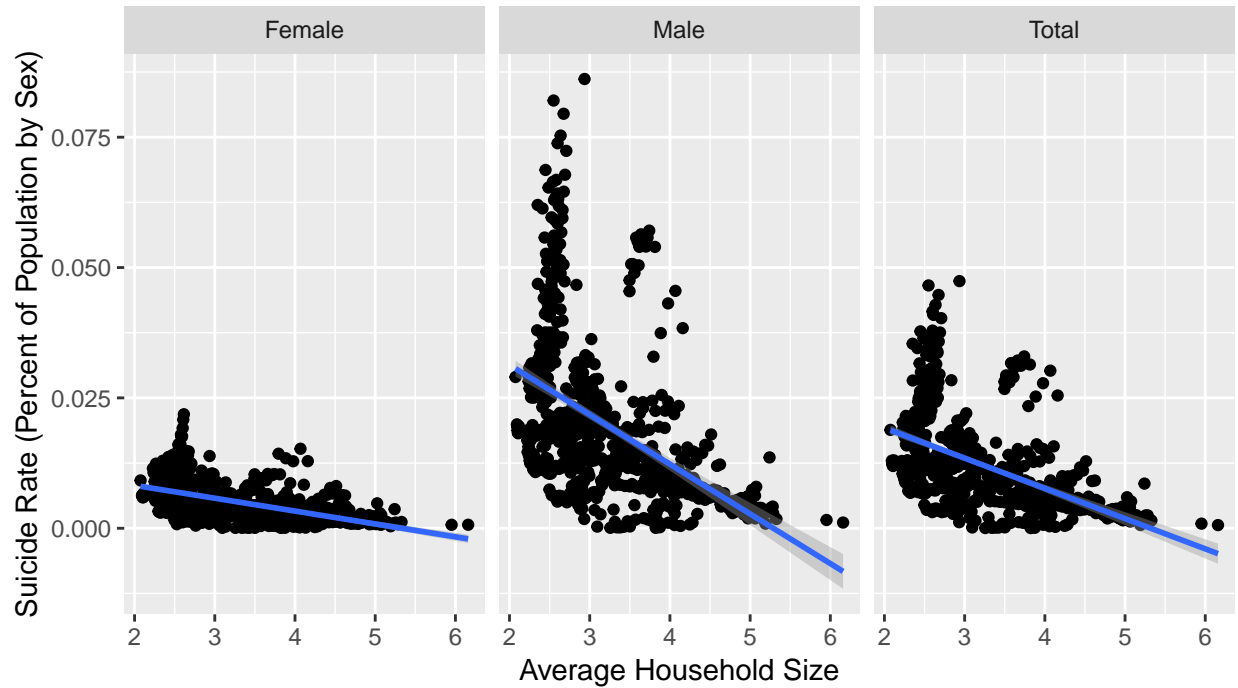

Based on data from WHO's Suicide Database and OECD's Family Database.
Suicide rates include only successful attempts.

Correlation of Average Household Size and Suicide Rates: This plot displaces a faceted scatter plot of the average household size (in number of people) and the suicide rate as a percent of the population. This scatter plot is faceted by female, male, and total suicide rates. The blue line is a line of best fit with a polynomial degree of 1. This shows a strong trend amongst people that living with others deters suicide. We had initially thought that males and females might display different preferences in this regard, but it appears that those preferences at least do not present themselves in the suicide rates.

Correlation of Average Household Size and Suicide Rates

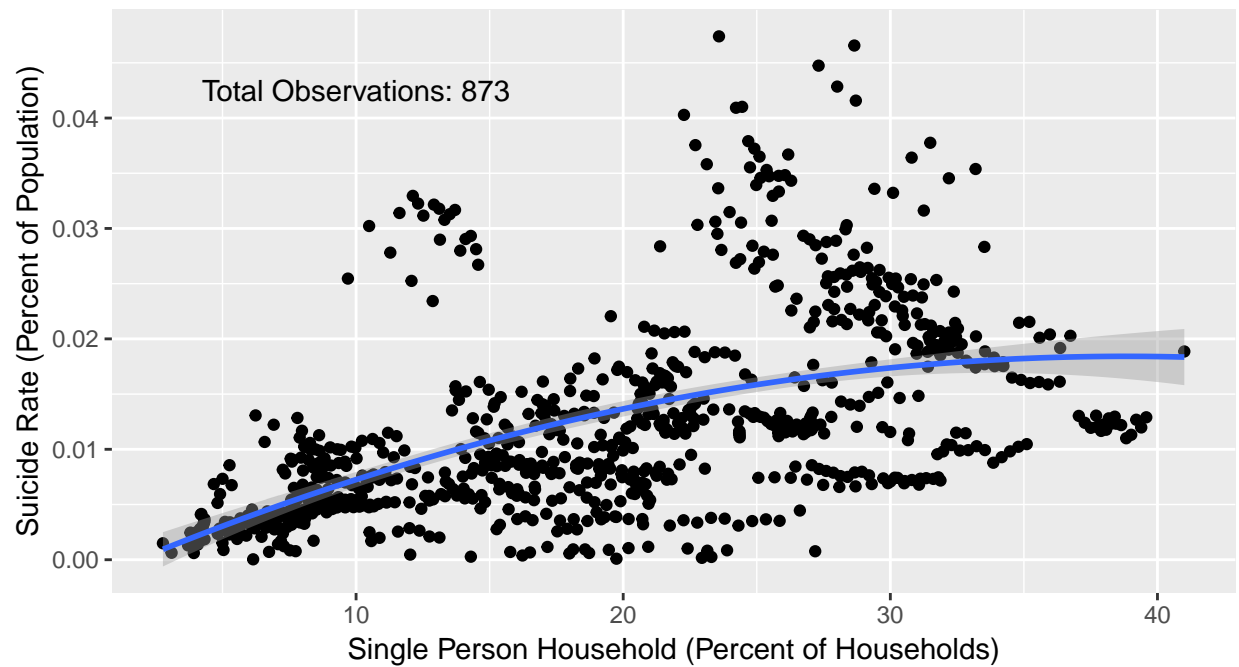

By Country Years [Total Observations: 2544]

Based on data from WHO's Suicide Database and UN DESA's Population dataset.
Suicide rates include only successful attempts.

Correlation of Single Households and Suicide Rates Plot: This plot displays a scatter plot of the percent of households consisting of a single person to the suicide rate as a percent of the population. The blue line is a line of best fit with a polynomial degree of 2. This shows a strong trend towards higher suicide rates as more people live alone. While we see the line start to dip at the highest rates of single person households, the amount of data in that area is small and the uncertainty of that dip is great. Thus, there is no reason then to believe that the suicide rate will not have a positive derivative (will increase) at all values of single person household rates.

Correlation of Single Households and Suicide Rates By Country Year

Based on data from WHO's Suicide Database and UN DESA's Population dataset.
Suicide rates include only successful attempts.
A single person households is not necessarily an unmarried household.
